1. INTRODUCTION

One of the most challenging weather forecast problems in the southeastern U.S. is daily summertime pulse convection. During the summer, atmospheric flow and forcing are generally weak in this region; thus, convection typically initiates in response to local forcing along sea/lake breezes, and other discontinuities often related to horizontal gradients in surface heating rates. Numerical simulations of pulse convection usually have low skill, even in local predictions at high resolution, due to the inherent chaotic nature of these precipitation systems. Forecast errors can arise from assumptions within physics parameterizations, model resolution limitations, as well as uncertainties in both the initial state of the atmosphere and land surface variables such as soil moisture and temperature. For this study, it is hypothesized that high-resolution, consistent representations of surface properties such as soil moisture, soil temperature, and sea surface temperature (SST) are necessary to better simulate the interactions between the surface and atmosphere, and ultimately improve predictions of local circulations and summertime pulse convection.

The Short-term Prediction Research and Transition (SPoRT) Center has been conducting studies to examine the impacts of high-resolution land surface initialization data generated by offline simulations of the NASA Land Information System (LIS; Kumar et al. 2006, 2007) on subsequent numerical forecasts using the Weather Research and Forecasting (WRF) model (Case et al. 2008b). The NASA LIS is a high performance land surface modeling and data assimilation system that integrates satellite-derived datasets, ground-based observations and model reanalyses to force a variety of land surface models (LSMs). By using scalable, high-performance computing and data management technologies, LIS can run LSMs offline globally with a grid spacing as fine as 1 km to characterize land surface states and fluxes. Case et al. (2008b) presented improvements to simulated sea breezes and surface verification statistics over Florida by initializing the WRF model with land surface variables from an offline LIS spin-up run, conducted on the same WRF domain and resolution. In addition, Case et al. (2008c) demonstrated the ability to use both LIS land surface fields and high-resolution SSTs to initialize the surface and sub-surface variables over a coastal domain, thereby providing a high-resolution lower boundary initial condition over the entire modeling domain.

The SPoRT Center has also developed high-resolution SST composites derived from the Moderate Resolution Imaging Spectroradiometer (MODIS) instruments aboard the NASA Aqua and Terra polar-orbiting satellites (Haines et al. 2007). The SPoRT Center has demonstrated the exquisite detail that can be depicted by these four-times-per-day composites compared to the once daily operational Real-Time Global (RTG) product used by the National Centers for Environmental Prediction (NCEP) models, which has a substantial impact on horizontal gradients in modeled sensible and latent heat fluxes over water bodies (LaCasse et al. 2008; Case et al. 2008a). They have also examined the sensitivity of WRF model simulations over oceanic regions to the high-resolution information, depicting the modifications to the nocturnal marine boundary layer under certain flow regimes over Florida. For example, LaCasse et al. (2008) depicted decreased static stability near the Florida East Coast under easterly flow regimes, and favored zones of low-level convergence near the coast under easterly flow and over the Gulf Stream under westerly flow. These model sensitivities to SSTs can have important implications to operations by providing modeled Planetary Boundary Layer (PBL) interactions with the detailed SSTs not currently available with any national or global product.

This current project extends the previous work done over Florida, now focusing on cases of typical pulse convection over the southeastern U.S., with an emphasis on improving the local short-term WRF simulations. This modeling study makes use of both the LIS land surface initialization and SPoRT MODIS SSTs to examine the sensitivity and possible improvements realized from these NASA capabilities. Furthermore, this study serves as a proof of concept to show that LIS and MODIS SST data can be easily incorporated into WRF for the benefit of organizations interested in running a local WRF application. The remainder of this paper is organized as follows. Section 2 provides some background information on the SPoRT Center and its programmatic and technical objectives. Section 3 describes the methodology for the current sensitivity experiment. Preliminary results are presented in Section 4, and a summary and vision for future work is given in Section 5.
2. THE NASA SPORT CENTER

The NASA SPoRT Center at the Marshall Space Flight Center (MSFC) seeks to accelerate the infusion of NASA Earth Science observations, data assimilation, and modeling research into weather forecast operations and decision-making at the regional and local level. It directly supports the NASA strategic plan of using results of scientific discovery to directly benefit society. The program is executed in concert with other government, university, and private sector partners. The primary focus is on the regional scale and emphasizes forecast improvements on a time scale of 0–24 hours. The SPoRT Center has facilitated the use of real-time NASA data and products to 13 National Weather Service (NWS) Weather Forecast Offices (WFOs) and several private weather entities primarily in the southeast United States. Numerous new techniques have been developed to transform satellite observations into useful parameters that better describe changing weather conditions.

The unique weather products have helped local WFOs improve forecasts of reduced visibility due to fog, low clouds, and smoke and haze from sources such as forest fires and agricultural burning, the onset of precipitation, the occurrence and location of severe weather events, and other local weather changes. Additionally, high-resolution satellite data provided by SPoRT has been used by the private sector to inform the marine weather community of changing ocean conditions and with tropical storm and hurricane monitoring.

3. EXPERIMENT DESIGN

A modeling sensitivity experiment is conducted with version 3.0.1.1 of the Advanced Research WRF (ARW; Skamarock et al. 2008) in which the land and ocean/lake surface data from the NCEP North American Mesoscale (NAM) model is replaced with high-resolution data from a LIS offline simulation and MODIS SST composites, respectively. Details on the specific model configurations, initialization datasets, and verification methodologies are described below.

3.1 Model Configuration and Period of Study

This investigation consists of a set of Control and experimental ARW simulations initialized once per day at 0300 UTC from June to August 2008. The model is integrated 27 hours to 0600 UTC the following day, similar to some operational WRF runs done at NOAA/NWS Miami, FL and Mobile, AL. The simulation domain (depicted in Figure 1) consists of a single grid of 309 x 311 staggered points in the zonal and meridional directions, respectively, at 4-km horizontal grid spacing. The grid contains 39 sigma-pressure vertical levels extending from the surface to a domain top of 50 mb. The vertical spacing is stretched from a minimum of 0.004 sigma near the surface (corresponding to ~40 m) to a maximum of 0.034 sigma at upper levels.

For both the Control and LIS+MODIS-initialized simulations (hereafter LISMOD), the ARW physics options consist of the rapid radiative transfer model (Mlawer et al. 1997) and the Dudhia scheme (Dudhia 1989) for longwave and shortwave radiation, respectively. The WRF Single Moment 6-class microphysics scheme (WSM6, Hong and Lim 2006; Skamarock et al. 2008) is used without any convective parameterization physics; thus, all convection is determined explicitly by the WSM6 microphysics and model dynamics. The planetary boundary layer and turbulence processes are parameterized by the Mellor-Yamada-Janjić scheme (Janjić 1990, 1996, 2002). Horizontal diffusion is handled by the two-dimensional Smagorinsky first-order closure scheme (Smagorinsky et al. 1965). All WRF runs use the Noah LSM as configured in version 3.0.1.1 of the ARW, being nearly identical to the version run operationally at NCEP (Chen and Dudhia 2001; Skamarock et al. 2008; Ek et al. 2003). Surface-layer calculations of friction velocities and exchange coefficients needed for the determination of sensible and latent fluxes in the LSM are provided by the NCEP Eta similarity theory scheme (Janjić 1999, 2002). The positive-definite advection options for moisture and scalars are enabled to remove the possible unphysical effects and high precipitation bias that can result from the “clipping” of negative mixing ratios in the 3rd order Runge-Kutta transport scheme (Skamarock and Weisman 2008; Skamarock et al. 2008).

For the Control runs, all initial conditions for the atmosphere, land, and RTG SSTs come from the native-resolution (12-km, grib 218) NCEP NAM model 3-h forecast initialized at 0000 UTC. Three-hourly boundary conditions for both the Control and LISMOD runs are provided by the NAM model 3-h to 30-h forecasts. The SSTs remain fixed throughout the 27-h ARW simulations. Interpolation of initial and boundary condition data are done with the WRF Pre-Processing System (WPS) utilities.

3.2 Initialization Data in Experimental Simulations

The LISMOD experimental runs are identical to the Control configuration except for the land surface initialization fields and the fixed SSTs. The land surface initial conditions of the Control are replaced by output from an offline LIS spin-up run. Meanwhile, the fixed RTG SSTs of the NAM model are replaced by the high-resolution SPoRT MODIS SST composites. Details on the LIS land surface and MODIS SST data, and how the data are incorporated into WRF are described in the sub-sections below.

3.2.1 LIS Initialization Data

For the offline LIS run, version 2.7.1 of the Noah LSM is run in LIS version 5 at the same horizontal resolution and center point as the WRF grid, but on a slightly larger domain to demonstrate that the WPS utilities can adequately interpolate the LIS data. Ideally, the LIS grid setup would be identical to the WRF simulation domain to avoid inconsistencies between the LIS and WRF soil fields introduced by horizontal interpolation. However, we aim to demonstrate a possible operational configuration in which SPoRT provides a generalized LIS initialization dataset to a variety of users (e.g. various NWS WFOs) running their own local WRF applications on domains that do not necessarily match the LIS grid. Such a scenario is
probably the most practical method for providing LIS initialization data to multiple users.

For consistency, the Noah LSM in the offline LIS run uses the same soil and vegetation database as used by the WRF model. The soil type and properties are represented by the State Soil Geographic (STATSGO; Miller and White 1998) database. For the land-water mask and land cover, the U.S. Geological Survey 1-km global database derived from the Advanced Very High Resolution Radiometer (AVHRR) satellite data from 1992–1993 is up-scaled to the 4-km grid.

Additional required parameters used in the offline LIS runs include quarterly climatologies of albedo (Briegleb et al. 1986) and maximum snow-free albedo (Robinson and Kukla 1985), monthly climatologies of greenness fraction data derived from the AVHRR satellite (Gutman and Ignatov 1998), and a deep soil temperature climatology (serving as a lower boundary condition for the soil layers) at 3 meters below ground, derived from 6 years of Global Data Analysis System (GDAS) 3-hourly averaged 2-m air temperatures using the method described in Chen and Dudhia (2001).

The offline LIS run is cold-started on 1 January 2004 with a uniform first-guess soil temperature and moisture value. The Noah LSM is allowed to reach an equilibrium state during a spin-up integration of 4 years, 5 months from 1 January 2004 to 1 June 2008, using an integration time step of 30 minutes. Atmospheric forcings for the LIS run are provided by GDAS analyses (Derber et al. 1991). The GDAS has global coverage with three-hourly data at a horizontal resolution of 0.469° (~52 km). In addition, supplemental precipitation forcing from the Stage IV high-resolution analyses replaces the GDAS precipitation, providing much more detailed precipitation fields than GDAS. The Stage IV product consists of hourly ~4-km precipitation analyses produced operationally by the U.S. River Forecast Centers, based on rain gauges and radar precipitation estimates from the Weather Surveillance Radar-1988 Doppler network (Lin and Mitchell 2005; Lin et al. 2005). The forcing fields are down-scaled to the running resolution in LIS using bilinear or conservative (for precipitation) interpolation approaches. In the case of downward shortwave radiation, an additional zenith-angle based temporal disaggregation is applied. The forcing fields of downward-directed longwave radiation, pressure, 2-m air temperature and 2-m relative humidity are further topographically corrected via lapse-rate and hypsometric adjustments using the elevation data differences between the LIS grid and the native GDAS forcing grid.

The LIS is output in Gridded Binary-I format (GRIB1) daily at 0300 UTC for the period of record (June – August 2008) to initialize the WRF land surface fields in the LISMOD simulations. The GRIB1 formatted LIS data is used by the WPS with only a few minor modifications required. First, the output units in LIS soil moisture are changed to volumetric water content to be consistent with the units used in WPS/WRF. Second, the GRIB1 file “METGRID.TBL” is modified to handle the LIS land-sea mask for interpolation of data to the WRF grid. The new LIS land-sea mask defined in METGRID.TBL is then applied to each of the land surface variables to be interpolated to the WRF grid. Finally, the interpolation method used in WPS for the LIS fields is a nearest-neighbor approach, as this method preserves the most detail and minimizes differences caused by interpolation. A summary of all the LIS fields incorporated into the WRF initial conditions is given in Table 1.

### 3.2.2 MODIS Sea Surface Temperatures

A 1-km MODIS SST composite, produced at the NASA SPoRT Center, is created by combining multiple passes of the Earth Observing System MODIS SST data (Haines et al. 2007). The compositing assumes that the day-to-day variation of SST is relatively small — the degree to which this assumption is valid will likely vary spatially and seasonally. Data from both the Terra and Aqua platforms are combined to create separate day/night composites. The composites examine the five most recent clear-sky SST values at each pixel. It then averages the warmest three of these five pixels in order to minimize the impact of cloud contamination.

Daytime (nighttime) passes through the composite region occur at approximately 1600 and 1900 UTC (0400 and 0700 UTC), respectively. The composites are output in GRIB1 format to ensure a seamless interpolation to the WRF grid with the WPS programs. Prior to being interpolated to the WRF grid, however, each 1-km MODIS SST composite is sub-sampled to a coarser grid with 2-km horizontal grid spacing due to limitations in array dimensions of the GRIB1 format.

Finally, the MODIS composite from 0400 UTC the previous day is incorporated into the daily WRF initial conditions at 0300 UTC to minimize diurnal variations in SST relative to the model initialization time. The only exception occurs for model initializations from 3–14 June 2008, when data are missing for the 0400 UTC MODIS composites. For these LISMOD model initializations, the 0700 UTC MODIS composites from the previous day are used to initialize the SSTs.

### 3.3 Verification Methodology and Tools

For verifying precipitation and other fields in both the Control and LISMOD runs, the Meteorological Evaluation Tools (MET) package is employed. Created by the WRF Developmental Testbed Center at the National Center for Atmospheric Research, the MET package is a highly-configurable, state-of-the-art suite of model verification tools. It was developed using output from WRF but may be applied to the output of other modeling systems as well. MET provides a variety of verification techniques, including:

- Standard verification scores comparing gridded model data to point observations,
- Standard and neighborhood verification scores comparing gridded model data to gridded observations, and
- Object-based verification method comparing gridded model data to gridded observations.

Our objectives for using MET at NASA/SPoRT is to incorporate a more standardized verification platform from which to conduct model evaluations. For this specific project, we are especially interested in capitalizing on the object-oriented verification methodology that has been implemented in MET. Known as the Method for Object-based Diagnostic Evaluation (MODE; Brown et al. 2007; Davis et al. 2009), this utility classifies “objects” in gridded fields, calculates a wide variety of object attributes, and merges/pairs forecast objects with observed objects to determine the similarities and differences between the various objects. We apply this utility to obtain more meaningful precipitation verification statistics for high-resolution forecasts of the pulse-type convection over the southeastern U.S.

4. PRELIMINARY RESULTS

This section provides preliminary results that illustrate some of the differences between the LIS land surface and MODIS SST initialization versus the interpolated NAM data in the Control runs. Sample forecast impacts are presented, as well as output from the MODE analysis tool available in the MET verification package.

4.1 LIS Offline Run Results from T.S. Fay

A high-impact event that affected the domain during the period of record is Tropical Storm Fay in late August. In the 8-day period from 18–26 August, the storm produced prodigious amounts of rainfall across eastern and northern Florida, southwestern Georgia, and Alabama (Figure 2), with some local maxima exceeding 700 mm.

Needless to say, the volumetric soil moisture increases dramatically during this 8-day period over the affected areas. The root zone layer in the Noah LSM (40–100 cm) should have a substantial impact on the subsequent evapo-transpiration into the atmosphere. Figure 3 depicts the moistening of the 40–100 cm soil layer from 18–26 August, comparing changes in the Control initialization (Figure 3a) to the LISMOD initialization (Figure 3b). Both model initialization differences show a similar broad pattern of moistening from Florida and southern Georgia into east-central Mississippi that follows the general pattern of rainfall depicted in Figure 2. The LISMOD differences have much more detail as expected; however, the LISMOD (Figure 3b) has substantially higher amounts of moistening across much of the eastern Florida peninsula, which correlates much better to the pattern of the rainfall maximum in Figure 2 compared to the Control (Figure 3a).

A LIS/Noah time-depth cross section at a selected point in southwestern Georgia (Figure 4) helps to illustrate the dramatic soil moistening associated with Tropical Storm Fay. In about a day, the volumetric soil moisture in the upper 1 meter increases from a minimum of less than 6% to a maximum value near 40%. Such a sudden shift from excessively dry to moist can have substantial impacts on the surface energy budget and subsequent short-term forecasting issues. It is therefore important to be able to capture accurately the rapid changes to the soil moisture field in such situations in order to improve subsequent short-term numerical simulations.

4.2 Differences in Surface Initialization Datasets

The combination of LIS spin-up data and MODIS SSTs provides a considerably more detailed representation of the land and water surface compared to the Control run using interpolated 12-km NAM data. The depiction of 0–10 cm soil moisture at 0300 UTC 10 June 2008 in Figure 5 helps to illustrate this point. While the regional patterns of soil moisture are fairly similar, the LISMOD initialization data provides information more consistent with the resolution of the WRF model in Figure 5b.

The difference field also indicates systematically drier initial conditions in this soil layer from southern Mississippi to northwestern South Carolina (Figure 5c). Over Florida, drier soil moisture is interspersed with local pockets of wetter soil moisture. These soil moisture variations are likely attributed to differences between the 12-km NAM Data Assimilation System (NDAS), which front-ends the NAM model, and the GDAS, which forces the LIS off-line run in combination with the Stage-IV precipitation analyses. Also, the ability of the 4-km LIS to better capture local areas of convective-type precipitation compared to the 12-km NDAS explains the local variations in soil moisture over Florida. It should be noted that the NDAS also uses the Stage-IV precipitation product to initialize its soil fields, similar to our offline LIS run.

Meanwhile over the adjacent waters, the SPoRT MODIS SST product provides much more detail over the Gulf of Mexico and Atlantic waters compared to the interpolated RTG SSTs from the NAM model (Figure 6). For the model run initialized at 0300 UTC 10 June, SSTs were obtained from the 0700 UTC 9 June SPoRT/MODIS composite. Substantial differences (up to 2°C) are found in the vicinity of the shallow near-coastal waters near the Florida coast. For this particular composite, the MODIS tends to be cooler than the RTG.

The most noteworthy aspect of the MODIS composite is its ability to capture the fine-scale horizontal gradients in SSTs compared to the once-daily RTG product. The smoothness of the RTG data in Figure 6a precludes the model from capturing the relatively cool shelf waters off the Florida East Coast. However, the LISMOD SSTs in Figure 6b are able to depict the cool shelf waters and the magnitude of the Gulf Stream east of Florida. The SST differences illustrate the locally sharper horizontal gradients captured by the SPoRT MODIS product in Figure 6c.

4.3 Sample Forecast Sensitivities of Precipitation

At first glance, the precipitation forecast sensitivities appear somewhat subtle, despite relatively significant changes in the details of the land and water initial conditions. A qualitative examination of several different days during the period of record (not shown) indicates that the broad patterns of forecast precipitation in the Control and LISMOD runs are generally similar, especially at longer accumulation
intervals. Most of the differences in forecast precipitation arise from small-scale fluctuations in individual convective elements that evolve differently due to the variations in the land/water surface interactions with the PBL. If the Control forecast is significantly in error with the large-scale precipitation features, then the LISMOD is also generally in error. Therefore, it appears that the forecast precipitation in this model configuration is still largely driven by the atmospheric initial and boundary conditions, in addition to model dynamics and physics.

A sample 1-h forecast precipitation comparison ending 2100 UTC 10 June 2008 is presented in Figure 7. The flow pattern was very weak on this day, with no discernable boundaries or organized flow pattern over the southeastern U.S. Figure 7 shows how the forecast 1-h precipitation patterns and modes are quite similar overall in the Control and LISMOD runs. However, the difference field depicts numerous small-scale fluctuations between the forecasts (Figure 7c). Compared to the Stage-IV product in Figure 7d, both simulations over-predict precipitation across portions of Georgia and Mississippi, while under-predicting stratiform-type rainfall over northern Florida. So, it appears that the high-resolution input from LIS and MODIS SSTs led to numerous small-scale variations in the convective precipitation pattern, while the overall pattern of simulated precipitation remained nearly the same.

4.4 Selected Traditional Verification Statistics

Traditional point verification statistics at approximately 500 primary, mesonet, and cooperative stations over the southeastern U.S. were calculated using the MET package. The bias and RMS errors as a function of forecast hour (Figure 8a and b, respectively) for 2-m temperature and dew point temperature reveal relatively minor differences in most forecast hours. The bias plots (Figure 8a) indicate that the LISMOD develops a slightly higher warm bias by a few tenths of a degree Celsius between forecast hours 9 and 18, while a nominal dry dew point bias ≤ 0.5°C occurs between forecast hours 9 and 27. The total error represented by the RMS error in Figure 8b shows only very small differences between Control and LISMOD, with the LISMOD having marginally larger errors.

Using traditional grid-point by grid-point techniques, the 1-hour accumulated precipitation errors were also calculated using MET tools during the forecast hours of typical peak convective activity (12–24 hours, corresponding to 1500–0300 UTC). The results indicate that both the Control and LISMOD over-predict the area coverage of 1-hour accumulated precipitation at all 3 thresholds examined (bias > 1 for 5-, 10-, and 25-mm per hour; Figure 9a). However, the LISMOD tends to reduce the bias between forecast hours 12–18, especially at the higher intensities. The Heidke Skill Score (HSS) in Figure 9b depicts a low skill under 0.10 for all precipitation thresholds that diminishes with forecast hour. The LISMOD has a marginally higher skill, mainly between forecast hours 12 and 18. Overall, the traditional error differences are quite minor and do not reveal any obvious performance differences in model accuracy, except for a reduction in the high-intensity precipitation bias.

4.5 MODE Object-Based Verification

The remainder of the analysis focuses on the non-traditional object-based verification available from MET’s MODE tool. We first present a snapshot of forecast/observed object pairs from the Control and LISMOD simulation from 10 June, followed by overall composite results from running MODE over all 81 Control and LISMOD forecasts from summer 2008.

The object-matching in MODE is centered on an “interest function”, which combines several attributes about the feature of interest — in this case 1-h accumulated precipitation from the WRF model (forecast) and Stage IV precipitation analyses (observed). The attributes consist of object characteristics such as centroid distance, minimum boundary distance, orientation angle difference, etc. MODE resolves objects in a gridded field through convolution thresholding. This technique involves applying a filter function to the raw data using a tunable radius of influence. The filtered field is then thresholded using another tunable parameter (typically the precipitation threshold) to create a mask field. Finally, the raw data are restored to objects where the mask meets/exceeds the specified threshold. More information on the technical details of MODE can be gleaned from Brown et al. (2007), Davis et al. (2009), and the MET User’s Guide.

Forecast and observed objects are matched based on additional input criteria and a minimum value of the “interest function”, which scales between 0 and 1. Our analysis focuses on 10 mm (1 h)−1 precipitation objects during the peak convective forecast hours (12–24 h). The fuzzy engine weights used to formulate the interest function in our case are given in Table 2. Forecast/observed objects are considered matches if the interest function is ≥ 0.6 and the distance between the object centroids is no greater than 80 km. The interest function is not calculated for object pairs whose centroids are greater than 80 km apart.

4.5.1 Output from 10 June 2008

Output from MODE for precipitation objects of 10 mm or greater for the 1-h period ending 2100 UTC 10 June is given in Figure 10. A comparison between the Control forecast and observed objects (Figure 10a, left column) shows about 4 small matched precipitation objects across the northern half of the Florida peninsula with several false alarm objects across southwestern Georgia, southeastern Alabama, and portions of south Florida. The LISMOD run has a similar pattern of 10-mm matched objects in northern Florida; however, there is a noticeable reduction in the false alarm objects over Georgia and Alabama.

It should be noted that if we had increased the object centroid distance criterion, modified the fuzzy weights in Table 2, and/or relaxed the interest function minimum threshold, then many more forecast and observed objects would have been matched together. For example, both the Control and LISMOD predicts 10-mm rainfall objects over the southeastern Florida coast
in the vicinity of the observed precipitation areas, but
the distances are too far to be considered matches.
We used such a stringent requirement in order to
minimize object matching for rainfall areas that a
forecaster would not consider a “hit” (e.g., rainfall on
the west coast of Florida being matched with objects on
the east coast). Despite the somewhat stringent
constraints placed on MODE, this configuration
appeared optimal based on the level of detail and
accuracy desired for this experiment.

Once the object matching is done, the total area
of matched and unmatched objects is provided at each
forecast hour in the MODE output. A summary of the
matched/unmatched objects areas (with forecast and
observed objects combined together) indicates that the
LISMOD out-performed the Control run on this day at
many of the forecast hours (Table 3). Nine of the 13
hourly forecast periods have reductions in the
unmatched areas in LISMOD, while 6 forecast hours
have increases in the total matched area. Meanwhile,
the Control experiences only 2 hourly forecasts with
improvements in the matched/unmatched area over the
LISMOD.

4.5.2 MODE Verification for Summer 2008

By applying the same object matching criteria to all
81 forecasts for the summer 2008, we can determine
whether the LISMOD consistently out-performed the
Control in 1-h precipitation forecasting accuracy during
the peak convective hours. A summary of the mean
matched/unmatched object areas per forecast run is
provided in Table 4. For all 81 simulations combined,
the LISMOD produces on average 4.3% more matched
and 3.8% fewer unmatched object areas compared to
the Control for the 10 mm (1 h)\(^{-1}\) threshold between
forecast hours 12-24. The statistical significance of
these numbers has not yet been computed, but with a
sample size in the thousands, the results appear clear
that LISMOD yields a measurable improvement over
the Control.

During the peak convective times, the LISMOD
consistently produces a slight increase in the matched
area and a slight decrease in the unmatched area as a
function of forecast hour (Figure 11a). The percentage
change in matched/unmatched area indicates the
greatest improvement earlier in the day between
forecast hours 12 and 19 (Figure 11b). It should be
noted that the 5-mm (1 h)\(^{-1}\) also shows a notable
improvement in the LISMOD, mainly from a reduction in
unmatched area (not shown). However, the 25-mm (1 h)\(^{-1}\)
threshold did not show much of a clear distinction
between the Control and LISMOD as a function of
forecast hour.

Figure 12 provides a summary of the overall
distribution of interest function values between forecast
and object pairs at all forecast hours between
1500–0300 UTC for all 81 forecast days. Higher
interest function values indicate that the forecast
objects tend to be more similar in attributes to the
corresponding observed objects. Among the three
precipitation thresholds presented in Figure 12, the
LISMOD has a larger interest value at higher percentiles in the distribution, particularly for the more
intense precipitation thresholds. The LISMOD has a
consistently higher interest value nearly everywhere in
the distribution for the 25-mm threshold, and from the
50th to 90th percentiles for 10-mm threshold. The 5-
mm interest values show little overall difference
between Control and LISMOD. This result suggests
that the LISMOD forecasts produced 1-hour
accumulated precipitation areas that more closely
resemble the observed rainfall areas, especially for
more intense thresholds.

Finally, the accumulated precipitation in 3-hourly
intervals was also examined using MODE, but did not
show any distinctive signal between the Control and
LISMOD (not shown). It could be that convective
rainfall accumulation over a longer time period is
difficult to discern into meaningful objects when the
individual convective elements are somewhat random
and chaotic in terms of the development and evolution.

5. SUMMARY AND FUTURE WORK

This paper describes a sensitivity experiment in
which the interpolated land and ocean surface fields
from the NCEP NAM model in a Control WRF model
simulation are replaced with high-resolution datasets
provided by unique NASA assets in an experimental
simulation: the LIS and SPoRT/MODIS SSTs. The LIS
is run in an offline mode for several years at the same
grid resolution as the WRF model in order to provide
WRF with compatible land surface initial conditions in
an equilibrium state. The MODIS SSTs provide more
detailed analyses of the SSTs over the oceans and
large lakes compared to the RTG product used in the
Control model runs.

Preliminary results indicate the LISMOD initial
conditions contain much more detail, consistent with the
WRF model resolution (as expected), when compared
to the Control initial conditions. The large-scale
patterns of soil moisture are fairly similar, but the
LISMOD initial conditions do have some systematic
regional differences, probably due to the LIS better
resolving the fine-scale precipitation features of the
Stage IV data compared to the 12-km NDAS. The
MODIS SSTs are able to better capture the spatial
variability in SSTs, especially in the waters surrounding
the Florida peninsula. The forecast precipitation fields
are fairly similar, especially in the overall larger-scale
patterns; however, numerous small-scale differences
occur.

Traditional verification methods do not reveal
substantial differences between the two forecast
configurations. Only slight differences in the 2-m
temperature and dew point temperature errors are
evident. The traditional grid point precipitation
verification does show a small reduction in the over-
prediction of rainfall areas in LISMOD; however, the skill
is almost equally as low in both experiments. Output
from MODE’s object-based verification within the MET
package reveals that the LISMOD consistently
generated precipitation objects that better matched
observed precipitation objects, especially at higher
precipitation intensities. The LISMOD runs also
produced on average a 4% increase in matched
precipitation areas and a simultaneous 4% decrease in
unmatched areas (i.e. combination of false alarm and forecast misses).

Future efforts will include verifying the LIS soil moisture and temperature fields at Soil Climate Analysis Network sites over the southeastern U.S. In addition, we plan to examine the impacts of assimilating remotely-sensed and/or in situ soil moisture data, and introducing bi-weekly MODIS greenness vegetation fraction composites (as opposed to monthly climatologies) into offline NASA LIS runs and WRF simulations. Finally, the offline LIS runs could be transitioned into an operational mode similar to the MODIS SST composites, by providing high-resolution land surface fields and initialization data to NWS forecast offices in near real time.

6. ACKNOWLEDGEMENTS/DISCLAIMER

This research was funded by Dr. Tsengdar Lee of the NASA Science Mission Directorate’s Earth Science Division in support of the SPoRT program at the NASA MSFC. Computational resources for this work were provided by the NASA Center for Computational Sciences at the NASA Goddard Space Flight Center. The lead author is also indebted to the invaluable assistance provided by John Halley-Gotway and others on the MET development team at NCAR.

Mention of a copyrighted, trademarked or proprietary product, service, or document does not constitute endorsement thereof by the authors, ENSCO Inc., SAIC, USRA, the SPoRT Center, the National Aeronautics and Space Administration, or the United States Government. Any such mention is solely for the purpose of fully informing the reader of the resources used to conduct the work reported herein.

*Canopy water is initialized to “0” in the default WRF source code.
Figure 2. Total rainfall in mm from Tropical Storm Fay, accumulated from 0000 UTC 18 August to 0000 UTC 26 August 2008.

Figure 3. Change in volumetric soil moisture in the Noah 40–100 cm layer for the 0300 UTC WRF initializations from 18–26 August 2008, valid for the (a) Control run, and (b) LISMOD run. The ‘X’ denotes the location of the time-depth cross section displayed in Figure 4.
Figure 4. Time-depth cross section of LIS/Noah volumetric soil moisture at 31°N, 84°W (denoted by the ‘X’ in Figure 3b over southwestern Georgia).
Figure 5. Comparison between WRF-initialized 0–10 cm volumetric soil moisture for the (a) Control (NAM model), (b) LIS (LIS spin-up), and (c) difference field (LISMOD – Control) valid at 0300 UTC 10 June 2008.
Figure 6. Comparison between WRF static SSTs for the (a) Control (NAM model / RTG product), (b) LISMOD (SPoRT MODIS data), and (c) difference field (LISMOD – Control), valid for the model run initialized at 0300 UTC 10 June 2008.
Figure 7. Comparison of accumulated precipitation (mm) for the 1-h period ending 2100 UTC 10 June 2008 for the (a) Control run, (b) LISMOD run, (c) difference between LISMOD and Control, and (d) Stage IV precipitation. Traditional grid point verification methods yield a Heidke Skill Score of 0 for the Control run and 0.015 for the LISMOD run over this time interval.
Figure 8. Comparison of 2-m temperature and dew point temperature model errors (°C) for 81 Control and LISMOD forecasts from June–August 2008 at approximately 500 surface observation locations. Plots shown are (a) mean error (bias), and (b) Root Mean Square Error (RMSE).

Figure 9. Traditional verification metrics of 1-h accumulated precipitation during the peak convective hours of 1500 UTC to 0300 UTC (forecast hours 12–24) for all 81 forecasts in the study period (June to August 2008). Plots shown are (a) Bias, and (b) Heidke Skill Score (HSS), according to the legend provided.

Figure 10. Comparison of 18-h forecast and Stage IV (observed) ≥10-mm accumulated precipitation objects for the 1-h period ending 2100 UTC 10 June 2008 for the (a) Control run, and (b) LISMOD run. Solid blue shading indicates a false alarm in the forecast field or a forecast miss in the observed field. All other solid colors represent matched forecast or observed objects. Outlined blue areas denote the corresponding observed (forecast) objects in the field of forecast (observed) objects.
Table 3. Comparison between the total matched and unmatched areas (in number of grid points) of the 10-mm (1 h)$^{-1}$ precipitation objects in the Control and LISMOD runs initialized at 0300 UTC 10 June 2008. The valid times span from 1500 UTC 10 June to 0300 UTC 11 June. The better matched/unmatched numbers are in *bold-italics* font.

Figure 11. Comparison between the total matched and unmatched object areas from all 81 forecast cycles for 1-h accumulated precipitation ≥ 10 mm during the forecast hours centered on the diurnal peak convective activity (12−24 hours, valid 1500 UTC to 0300 UTC). (a) Total matched object area (blue bars) and unmatched object area (red bars) for the Control (solid bars) and LISMOD (hatched bars), and (b) LISMOD percentage change from the Control matched/unmatched object area.

Figure 12. Distribution of the total interest function for all 81 Control and LISMOD forecast/observed 1-h accumulated precipitation object pairs during the peak convective hours of 1500 to 0300 UTC. The plot depicts the Control and LISMOD values within their respective interest function distributions at the 10th, 25th, 50th, 75th, and 90th percentiles for 5-mm, 10-mm, and 25-mm accumulated precipitation thresholds, according to the scale provided. The interest function sample sizes are provided in Table 5.
Table 5. The number of 1-h accumulated precipitation object pairs at various thresholds composing the interest function distributions plotted in Figure 12.
